

## 14. Class

Classes are an expanded concept of data structures: like data structures, they can contain data members, but they can also contain functions as members.

An object is an instantiation of a class. In terms of variables, a class would be the type, and an object would be the variable.

Classes are defined using either keyword `class` or keyword `struct`, with the following syntax:

```
class class_name {
    access_specifier_1:
        member1;
    access_specifier_2:
        member2;
    ...
} object_names;
```

Where `class_name` is a valid identifier for the class, `object_names` is an optional list of names for objects of this class. The body of the declaration can contain members, which can either be data or function declarations, and optionally access specifiers.

Classes have the same format as plain data structures, except that they can also include functions and have these new things called access specifiers. An access specifier is one of the following three keywords: `private`, `public` or `protected`. These specifiers modify the access rights for the members that follow them:

- `private` members of a class are accessible only from within other members of the same class (or from their "friends").
- `protected` members are accessible from other members of the same class (or from their "friends"), but also from members of their derived classes.

Finally, `public` members are accessible from anywhere where the object is visible.

By default, all members of a class declared with the class keyword have private access for all its members. Therefore, any member that is declared before any other access specifier has private access automatically. For example:

```
class Rectangle {
    int width, height;
    public:
        void set_values (int,int);
        int area (void);
} rect;
```

Declares a class (i.e., a type) called Rectangle and an object (i.e., a variable) of this class, called rect. This class contains four members: two data members of type int (member width and member height) with private access (because private is the default access level) and two member functions with public access: the functions set\_values and area, of which for now we have only included their declaration, but not their definition.

Notice the difference between the class name and the object name: In the previous example, Rectangle was the class name (i.e., the type), whereas rect was an object of type Rectangle. It is the same relationship int and a have in the following declaration:

```
int a;
```

where int is the type name (the class) and a is the variable name (the object).

After the declarations of Rectangle and rect, any of the public members of object rect can be accessed as if they were normal functions or normal variables, by simply inserting a dot (.) between object name and member name. This follows the same syntax as accessing the members of plain data structures. For example:

```
rect.set_values (3,4);
myarea = rect.area();
```

The only members of rect that cannot be accessed from outside the class are width and height, since they have private access and they can only be referred to from within other members of that same class.

Here is the complete example of class Rectangle:

```
// classes example
#include <iostream>
```

```
using namespace std;

class Rectangle {
    int width, height;
public:
    void set_values (int,int);
    int area() {return width*height;}
};

void Rectangle::set_values (int x, int y) {
    width = x;
    height = y;
}

int main () {
    Rectangle rect;
    rect.set_values (3,4);
    cout << "area: " << rect.area();
    return 0;
}
```

```
area: 12
```

This example reintroduces the scope operator (::, two colons), seen in earlier chapters in relation to namespaces. Here it is used in the definition of function `set_values` to define a member of a class outside the class itself.

Notice that the definition of the member function `area` has been included directly within the definition of class `Rectangle` given its extreme simplicity. Conversely, `set_values` it is merely declared with its prototype within the class, but its definition is outside it. In this outside definition, the operator of scope (::) is used to specify that the function being defined is a member of the class `Rectangle` and not a regular non-member function.

The scope operator (::) specifies the class to which the member being defined belongs, granting exactly the same scope properties as if this function definition was directly included within the class definition. For example, the function `set_values` in the previous example has access to the variables `width` and `height`, which are private members of class `Rectangle`, and thus only accessible from other members of the class, such as this.

The only difference between defining a member function completely within the class definition or to just include its declaration in the function and define it later outside the class, is that in the first case the function is automatically considered an inline member function by the compiler, while in the second it is a normal (not-inline) class member

function. This causes no differences in behavior, but only on possible compiler optimizations.

Members `width` and `height` have private access (remember that if nothing else is specified, all members of a class defined with keyword `class` have private access). By declaring them private, access from outside the class is not allowed. This makes sense, since we have already defined a member function to set values for those members within the object: the member function `set_values`. Therefore, the rest of the program does not need to have direct access to them. Perhaps in a so simple example as this, it is difficult to see how restricting access to these variables may be useful, but in greater projects it may be very important that values cannot be modified in an unexpected way (unexpected from the point of view of the object).

The most important property of a class is that it is a type, and as such, we can declare multiple objects of it. For example, following with the previous example of class `Rectangle`, we could have declared the object `rectb` in addition to object `rect`:

```
// example: one class, two objects
#include <iostream>
using namespace std;

class Rectangle {
    int width, height;
public:
    void set_values (int,int);
    int area () {return width*height;}
};

void Rectangle::set_values (int x, int y) {
    width = x;
    height = y;
}

int main () {
    Rectangle rect, rectb;
    rect.set_values (3,4);
    rectb.set_values (5,6);
    cout << "rect area: " << rect.area() << endl;
    cout << "rectb area: " << rectb.area() << endl;
    return 0;
}
```

```
rect area: 12
rectb area: 30
```

In this particular case, the class (type of the objects) is `Rectangle`, of which there are two instances (i.e., objects): `rect` and `rectb`. Each one of them has its own member variables and member functions.

Notice that the call to `rect.area()` does not give the same result as the call to `rectb.area()`. This is because each object of class `Rectangle` has its own variables `width` and `height`, as they -in some way- have also their own function members `set_value` and `area` that operate on the object's own member variables.

Classes allow programming using object-oriented paradigms: Data and functions are both members of the object, reducing the need to pass and carry handlers or other state variables as arguments to functions, because they are part of the object whose member is called. Notice that no arguments were passed on the calls to `rect.area` or `rectb.area`. Those member functions directly used the data members of their respective objects `rect` and `rectb`.

## 14.1 Constructors

What would happen in the previous example if we called the member function `area` before having called `set_values`? An undetermined result, since the members `width` and `height` had never been assigned a value.

In order to avoid that, a class can include a special function called its constructor, which is automatically called whenever a new object of this class is created, allowing the class to initialize member variables or allocate storage.

This constructor function is declared just like a regular member function, but with a name that matches the class name and without any return type; not even `void`.

The `Rectangle` class above can easily be improved by implementing a constructor:

```
// example: class constructor
#include <iostream>
using namespace std;

class Rectangle {
    int width, height;
public:
    Rectangle (int,int);
    int area () {return (width*height);}
};
```

```
};

Rectangle::Rectangle (int a, int b) {
    width = a;
    height = b;
}

int main () {
    Rectangle rect (3,4);
    Rectangle rectb (5,6);
    cout << "rect area: " << rect.area() << endl;
    cout << "rectb area: " << rectb.area() << endl;
    return 0;
}
```

```
rect area: 12
rectb area: 30
```

The results of this example are identical to those of the previous example. But now, class `Rectangle` has no member function `set_values`, and has instead a constructor that performs a similar action: it initializes the values of `width` and `height` with the arguments passed to it.

Notice how these arguments are passed to the constructor at the moment at which the objects of this class are created:

```
Rectangle rect (3,4);
Rectangle rectb (5,6);
```

Constructors cannot be called explicitly as if they were regular member functions. They are only executed once, when a new object of that class is created.

Notice how neither the constructor prototype declaration (within the class) nor the latter constructor definition, have return values; not even `void`: Constructors never return values, they simply initialize the object.

## 14.2 Overloading constructors

Like any other function, a constructor can also be overloaded with different versions taking different parameters: with a different number of parameters and/or parameters of different types. The compiler will automatically call the one whose parameters match the arguments:

```
// overloading class constructors
#include <iostream>
using namespace std;

class Rectangle {
    int width, height;
public:
    Rectangle ();
    Rectangle (int,int);
    int area (void) {return (width*height);}
};

Rectangle::Rectangle () {
    width = 5;
    height = 5;
}

Rectangle::Rectangle (int a, int b) {
    width = a;
    height = b;
}

int main () {
    Rectangle rect (3,4);
    Rectangle rectb;
    cout << "rect area: " << rect.area() << endl;
    cout << "rectb area: " << rectb.area() << endl;
    return 0;
}
```

```
rect area: 12
rectb area: 25
```

In the above example, two objects of class Rectangle are constructed: rect and rectb. rect is constructed with two arguments, like in the example before.

But this example also introduces a special kind constructor: the default constructor. The default constructor is the constructor that takes no parameters, and it is special because it is called when an object is declared but is not initialized with any arguments. In the example above, the default constructor is called for rectb. Note how rectb is not even constructed with an empty set of parentheses - in fact, empty parentheses cannot be used to call the default constructor:

```
Rectangle rectb; // ok, default constructor called
Rectangle rectc(); // oops, default constructor NOT called
```

This is because the empty set of parentheses would make of rectc a function declaration instead of an object declaration: It would be a function that takes no arguments and returns a value of type Rectangle.

## 14.3 Uniform initialization

The way of calling constructors by enclosing their arguments in parentheses, as shown above, is known as functional form. But constructors can also be called with other syntaxes:

First, constructors with a single parameter can be called using the variable initialization syntax (an equal sign followed by the argument):

```
class_name object_name = initialization_value;
```

More recently, C++ introduced the possibility of constructors to be called using uniform initialization, which essentially is the same as the functional form, but using braces ( { } ) instead of parentheses ( ( ) ):

```
class_name object_name { value, value, value, ... }
```

Optionally, this last syntax can include an equal sign before the braces.

Here is an example with four ways to construct objects of a class whose constructor takes a single parameter:

```
// classes and uniform initialization
#include <iostream>
using namespace std;

class Circle {
    double radius;
public:
    Circle(double r) { radius = r; }
    double circum() {return 2*radius*3.14159265;}
};

int main () {
    Circle foo (10.0); // functional form
    Circle bar = 20.0; // assignment init.
    Circle baz {30.0}; // uniform init.
    Circle qux = {40.0}; // POD-like

    cout << "foo's circumference: " << foo.circum() << '\n';
    return 0;
}
```

```
foo's circumference: 62.8319
```

An advantage of uniform initialization over functional form is that, unlike parentheses, braces cannot be confused with function declarations, and thus can be used to explicitly call default constructors:

```
Rectangle rectb; // default constructor called
Rectangle rectc(); // function declaration (default constructor NOT called)
Rectangle rectd{}; // default constructor called
```

The choice of syntax to call constructors is largely a matter of style. Most existing code currently uses functional form, and some newer style guides suggest to choose uniform initialization over the others, even though it also has its potential pitfalls for its preference of `initializer_list` as its type.

## 14.4 Member initialization in constructors

When a constructor is used to initialize other members, these other members can be initialized directly, without resorting to statements in its body. This is done by inserting, before the constructor's body, a colon (:) and a list of initializations for class members. For example, consider a class with the following declaration:

```
class Rectangle {
    int width,height;
    public:
    Rectangle(int,int);
    int area() {return width*height;}
};
```

The constructor for this class could be defined, as usual, as:

```
Rectangle::Rectangle (int x, int y) { width=x; height=y; }
```

But it could also be defined using member initialization as:

```
Rectangle::Rectangle (int x, int y) : width(x) { height=y; }
```

Or even:

```
Rectangle::Rectangle (int x, int y) : width(x), height(y) { }
```

Note how in this last case, the constructor does nothing else than initialize its members, hence it has an empty function body.

For members of fundamental types, it makes no difference which of the ways above the constructor is defined, because they are not initialized by default, but for member objects (those whose type is a class), if they are not initialized after the colon, they are default-constructed.

Default-constructing all members of a class may or may always not be convenient: in some cases, this is a waste (when the member is then reinitialized otherwise in the constructor), but in some other cases, default-construction is not even possible (when the class does not have a default constructor). In these cases, members shall be initialized in the member initialization list. For example:

```
// member initialization
#include <iostream>
using namespace std;

class Circle {
    double radius;
public:
    Circle(double r) : radius(r) { }
    double area() {return radius*radius*3.14159265;}
};

class Cylinder {
    Circle base;
    double height;
public:
    Cylinder(double r, double h) : base (r), height(h) {}
    double volume() {return base.area() * height;}
};

int main () {
    Cylinder foo (10,20);

    cout << "foo's volume: " << foo.volume() << '\n';
    return 0;
}
```

```
foo's volume: 6283.19
```

In this example, class Cylinder has a member object whose type is another class (base's type is Circle). Because objects of class Circle can only be constructed with a parameter, Cylinder's constructor needs to call base's constructor, and the only way to do this is in the member initializer list.

These initializations can also use uniform initializer syntax, using braces {} instead of parentheses ():

```
Cylinder::Cylinder (double r, double h) : base{r}, height{h} { }
```

## 14.5 Pointers to classes

Objects can also be pointed to by pointers: Once declared, a class becomes a valid type, so it can be used as the type pointed to by a pointer. For example:

```
Rectangle * prect;
```

is a pointer to an object of class Rectangle.

Similarly as with plain data structures, the members of an object can be accessed directly from a pointer by using the arrow operator (->). Here is an example with some possible combinations:

```
// pointer to classes example
#include <iostream>
using namespace std;

class Rectangle {
    int width, height;
public:
    Rectangle(int x, int y) : width(x), height(y) {}
    int area(void) { return width * height; }
};

int main() {
    Rectangle obj (3, 4);
    Rectangle * foo, * bar, * baz;
    foo = &obj;
    bar = new Rectangle (5, 6);
    baz = new Rectangle[2] { {2,5}, {3,6} };
    cout << "obj's area: " << obj.area() << '\n';
    cout << "*foo's area: " << foo->area() << '\n';
    cout << "*bar's area: " << bar->area() << '\n';
    cout << "baz[0]'s area:" << baz[0].area() << '\n';
    cout << "baz[1]'s area:" << baz[1].area() << '\n';
    delete bar;
    delete[] baz;
    return 0;
}
```

```
obj's area: 12
```

```
*foo's area: 12
*bar's area: 30
baz[0]'s area:10
baz[1]'s area:18
```

This example makes use of several operators to operate on objects and pointers (operators `*`, `&`, `.`, `->`, `[ ]`). They can be interpreted as:

expression	can be read as
<code>*x</code>	pointed to by <code>x</code>
<code>&amp;x</code>	address of <code>x</code>
<code>x.y</code>	member <code>y</code> of object <code>x</code>
<code>x-&gt;y</code>	member <code>y</code> of object pointed to by <code>x</code>
<code>(*x).y</code>	member <code>y</code> of object pointed to by <code>x</code> (equivalent to the previous one)
<code>x[0]</code>	first object pointed to by <code>x</code>
<code>x[1]</code>	second object pointed to by <code>x</code>
<code>x[n]</code>	$(n+1)$ th object pointed to by <code>x</code>

Most of these expressions have been introduced in earlier chapters. Most notably, the chapter about arrays introduced the offset operator (`[ ]`) and the chapter about plain data structures introduced the arrow operator (`->`).

## 14.6 Default constructor

The default constructor is the constructor called when objects of a class are declared, but are not initialized with any arguments.

If a class definition has no constructors, the compiler assumes the class to have an implicitly defined default constructor. Therefore, after declaring a class like this:

```
class Example {
public:
    int total;
    void accumulate (int x) { total += x; }
};
```

The compiler assumes that Example has a default constructor. Therefore, objects of this class can be constructed by simply declaring them without any arguments:

```
Example ex;
```

But as soon as a class has some constructor taking any number of parameters explicitly declared, the compiler no longer provides an implicit default constructor, and no longer allows the declaration of new objects of that class without arguments. For example, the following class:

```
class Example2 {
    public:
        int total;
        Example2 (int initial_value) : total(initial_value) { };
        void accumulate (int x) { total += x; };
};
```

Here, we have declared a constructor with a parameter of type int. Therefore the following object declaration would be correct:

```
Example2 ex (100); // ok: calls constructor
```

But the following:

```
Example2 ex; // not valid: no default constructor
```

Would not be valid, since the class has been declared with an explicit constructor taking one argument and that replaces the implicit default constructor taking none.

Therefore, if objects of this class need to be constructed without arguments, the proper default constructor shall also be declared in the class. For example:

```
// classes and default constructors
#include <iostream>
#include <string>
using namespace std;

class Example3 {
    string data;
    public:
        Example3 (const string& str) : data(str) {}
        Example3() {}
        const string& content() const {return data;}
};
```

```
int main () {
    Example3 foo;
    Example3 bar ("Example");

    cout << "bar's content: " << bar.content() << '\n';
    return 0;
}
```

```
bar's content: Example
```

Here, Example3 has a default constructor (i.e., a constructor without parameters) defined as an empty block:

```
Example3() {}
```

This allows objects of class Example3 to be constructed without arguments (like foo was declared in this example). Normally, a default constructor like this is implicitly defined for all classes that have no other constructors and thus no explicit definition is required. But in this case, Example3 has another constructor:

```
Example3 (const string& str);
```

And when any constructor is explicitly declared in a class, no implicit default constructors is automatically provided.

## 14.7 Destructor

Destructors fulfill the opposite functionality of constructors: They are responsible for the necessary cleanup needed by a class when its lifetime ends. The classes we have defined in previous chapters did not allocate any resource and thus did not really require any clean up.

But now, let's imagine that the class in the last example allocates dynamic memory to store the string it had as data member; in this case, it would be very useful to have a function called automatically at the end of the object's life in charge of releasing this memory. To do this, we use a destructor. A destructor is a member function very similar to a default constructor: it takes no arguments and returns nothing, not even void. It also uses the class name as its own name, but preceded with a tilde sign (~):

```
// destructors
#include <iostream>
#include <string>
```

```
using namespace std;

class Example4 {
    string* ptr;
public:
    // constructors:
    Example4() : ptr(new string) {}
    Example4 (const string& str) : ptr(new string(str)) {}
    // destructor:
    ~Example4 () {delete ptr;}
    // access content:
    const string& content() const {return *ptr;}
};

int main () {
    Example4 foo;
    Example4 bar ("Example");

    cout << "bar's content: " << bar.content() << '\n';
    return 0;
}
```

```
bar's content: Example
```

On construction, Example4 allocates storage for a string. Storage that is later released by the destructor.

The destructor for an object is called at the end of its lifetime; in the case of foo and bar this happens at the end of function main.
